Conclusion

Program transformations

In the first week, we studied how to interpret functional programs.

This week, we compile them to lower-level code.

- This leads to more efficient execution. (No interpretive overhead.)
- This helps understand advanced language features, such as
  - first-class functions,
  - recursion,
  - exceptions, effect handlers, etc.
- This helps understand the organization of memory:
  - code versus data,
  - the stack versus the heap.
- This is an occasion to learn some programming techniques.
- This is an occasion to use operational semantics and discuss proofs.

Note: CPS, which explains "recursion" and "the stack", is optional reading.

Conclusion

Closure conversion apparatus for existing closure applicating machines

U.S. Patent   Oct. 20, 1981   Sheet 3 of 10   4,295,320

FIG. 3

Innovation in the carbonated beverage bottling industry is very much dependent on the ready availability of machinery for processing new types of containers and/or **closures**.

This invention provides substitute capping heads to apply a threaded closure on a bottle neck through the utilization of existing machines which were designed to apply an aluminum closure on a bottle neck by in situ formation of the threads in an aluminum shell.

MPRI FUN
Compiling
functions
away

François
Pottier

Motivation

We wish to compile (translate):

- a language with arbitrary first-class functions (i.e., λ-abstractions)

down to:

- a language with closed first-class functions (i.e., "code pointers")

Conclusion

Motivation

Why might we wish to understand this compilation technique?

- a key step in the compilation of functional programming languages;
- a way of explaining the magic of first-class functions;
- a way of understanding their space and time cost;
- a programming technique in languages without first-class functions.

Conclusion

Passing down a function

A functional programming language, such as OCaml, naturally allows:

- defining local (nested) functions,
- passing a function as an argument to a function.

This combination of features is sometimes known as "downward funargs".

```
let iter f a =
  for i = 0 to Array.length a - 1 do f a.(i) done
let sum a =
  let s = ref 0 in
  let add x = (s := !s + x) in
  iter add a;
  !s
```

add refers to the variable s, which is neither global nor local to add.

A nested function can refer to a local variable of an enclosing function.

Defun°

Digression
Objects
λ-lifting
SKI

Conclusion

Returning a function

A functional programming language also allows:

- returning a function out of a function;
- storing a function in a reference, for future use.

A nested function can thus outlive a local variable to which it refers.

This is sometimes called "upward funargs" (a strange name).

First-class functions have unbounded lifetimes;
therefore, their data cannot be stack-allocated.

Conclusion

Returning a function

A memory cell that is accessible only via a pair of `get` and `set` functions:

```
let make x =
  let cell = ref x in
  let get () = !cell
  and set  x = (cell := x) in
  get, set

let () =
  let get, set = make 3 in
  set (get() + 1)
```

A typical example of procedural abstraction (Reynolds, 1975),
which is widely popular in object-oriented programming languages.
On this topic, see also Cook (2009) and Aldrich (2013).

`cell` is a local variable in `make`.
It no longer exists when `get` and `set` are called!

How can we transform this code so as to use only closed functions? ...

Closure
conversion
Motivation
Definition
Soundness
Type preservat°
Digression

Defun°

Digression
Objects
λ-lifting
SKI

Conclusion

Principles of closure conversion

get and set need access to the value of the local variable cell.
(This value is the address of a heap-allocated reference cell.)

- Therefore, they need one more parameter, an environment, which somehow gives access to this value;

At a call site, we must be able to supply an environment.

- Therefore, a λ-abstraction must evaluate to a closure, which gives access to both the code and the environment.

A closure must be heap-allocated, as its lifetime is unbounded.

Conclusion

Variations

One must choose a convention as to

- the memory layout of the closure and environment,
- the calling convention of the code.

In the following, I make the following choices:

- the closure and the environment are the same memory block,
- the code expects a pair of the closure and the original argument.

Closure conversion: example

A closure `clo` is a pair of a function `code` and a pointer `cell`:

```
let closure code cell = (code, cell) (* builds a closure *)
let project_code = fst              (* reads the [code] field *)
let project_cell = snd              (* reads the [cell] field *)
```

The code expects a pair of the closure `clo` itself
and the original function argument `arg`.

```
let apply clo arg =
  let code = project_code clo in
  code (clo, arg)
```

Conclusion

Closure conversion: example

A closure `clo` is a pair of a function `code` and a pointer `cell`:

```
let closure code cell = (code, cell) (* builds a closure *)
let project_code = fst              (* reads the [code] field *)
let project_cell = snd              (* reads the [cell] field *)
```

The code expects a pair of the closure `clo` itself
and the original function argument `arg`.

```
let apply clo arg =
  let code = project_code clo in
  code (clo, arg)
```

This code is ill-typed in OCaml.

The closure `clo` contains a function `code` which expects the closure itself
as an argument. This is not permitted.

Conclusion

Closure conversion: example

The result of closure conversion is then as follows:

```
let make x =
  let cell = ref x in
  let get (clo, ()) = let cell = project_cell clo in !cell
  and set (clo,  x) = let cell = project_cell clo in cell := x
  in closure get cell, closure set cell

let () =
  let get, set = make 3 in
  apply set (apply get () + 1)
```

get and set are now closed functions: they have no free variables.

They can be hoisted out of make, if desired...

Conclusion

Complexity and cost model

Closure conversion leads to the following cost model:

- Evaluating a variable costs $O(1)$.

- Evaluating a λ-abstraction costs $O(n)$,
  where n is the number of its free variables.

- Evaluating an application costs $O(1)$.

n can be considered $O(1)$, as it depends only on the program's text,
not on the input data.

Conclusion

Which semantics for the target calculus?

Recall the standard big-step, environment-based semantics:

EBigCbvVar
$$\frac{e(x) = c}{e \vdash x \downarrow_{cbv} c}$$

EBigCbvLam
$$\frac{fv(\lambda x.t) \subseteq dom(e)}{e \vdash \lambda x.t \downarrow_{cbv} \langle \lambda x.t \mid e \rangle}$$

EBigCbvApp
$$\frac{e \vdash t_1 \downarrow_{cbv} \langle \lambda x.u_1 \mid e' \rangle \quad e \vdash t_2 \downarrow_{cbv} c_2 \quad e'[x \mapsto c_2] \vdash u_1 \downarrow_{cbv} c}{e \vdash t_1 \ t_2 \downarrow_{cbv} c}$$

where $c ::= \langle \lambda x.t \mid e \rangle$ and $e ::= [] \mid e[x \mapsto c]$.

How can this semantics be simplified?

$$\frac{fv(\lambda x.t) \subseteq \emptyset}{e \vdash \lambda x.t \Downarrow_{cbv} \lambda x.t}$$

MBIGCBVAPP
$$\frac{e \vdash t_1 \Downarrow_{cbv} \lambda x.u_1 \quad e \vdash t_2 \Downarrow_{cbv} c_2 \quad [][x \mapsto c_2] \vdash u_1 \Downarrow_{cbv} c}{e \vdash t_1 \ t_2 \Downarrow_{cbv} c}$$

where $c ::= \lambda x.t$ and $e ::= [] \mid e[x \mapsto c]$.

Such a semantics explains in what way the target calculus is simpler.

Exercise: extend this semantics with "*let*" constructs, pairs and projections. The solution is in `MetalBigStep`.

Conclusion

A semantic preservation statement

Semantic preservation is stated as follows:

Lemma (Semantic preservation)

Assume $e \vdash t \downarrow_{cbv} c$.
Then, $[\![e]\!] \vdash [\![t]\!] \Downarrow_{cbv} [\![c]\!]$ holds.

Exercise (recommended): write a careful proof of this lemma, on paper.

Conclusion

A semantic preservation statement

In Rocq, we use de Bruijn style, and prove:

Lemma (Semantic preservation)

Assume $e \vdash t \Downarrow_{cbv} c$.
Then, $[\![e]\!] \vdash [\![t]\!]_n \Downarrow\!\Downarrow_{cbv} [\![c]\!]$ holds,
where n is the length of the environment e.

Proof.

By induction on the hypothesis.
See `ClosureConversion/semantic_preservation`.   □

Here, the transformation $[\![\cdot]\!]$. takes two parameters t and n,
where the free variables of t are expected to be below n.

Exercise (tricky): define $[\![t]\!]_n$ and prove that if t has free variables below n
then $[\![t]\!]_n$ has free variables below n. See `ClosureConversion/fv_cc`.

Conclusion

Caveats

Are we happy with this semantic preservation statement?

$e \vdash t \downarrow_{cbv} c$ *implies* $[\![e]\!] \vdash [\![t]\!] \Downarrow_{cbv} [\![c]\!]$.

This is a forward preservation statement.

Does it actually mean what we think it means?

What do we think it means? Perhaps this?

*The transformed program "computes the same thing"
as the source program.*

Or this?

*The transformed program "behaves in the same way"
as the source program.*

Conclusion

Caveat 3: forward versus backward preservation

If the target calculus has deterministic semantics,
then the transformed program has exactly one behavior,
so forward and backward preservation coincide.

If the target calculus has nondeterministic semantics,
then backward preservation must be proved directly.

- A naïve approach may be painful.
- Relational Separation Logic is a tool that helps do this.

Conclusion

Understanding programs
through closure conversion

People sometimes use first-class functions in somewhat mysterious ways.

Closure conversion can help understand what is going on.

Let us look at a little example: difference lists.

This also illustrates type-preserving closure conversion in OCaml.

MPRI FUN
Compiling
functions

Conclusion

A fringe computation

Suppose we have a type of trees with integer-labeled leaves:

```
type tree =
  | Leaf of int
  | Node of tree * tree
```

Suppose we wish to construct a tree's fringe, a sequence of integers:

```
let rec fringe (t : tree) : int list =
  match t with
  | Leaf i        -> [ i ]
  | Node (t1, t2) -> fringe t1 @ fringe t2
```

What do you think?

Conclusion

Difference lists

To remedy this, people sometimes use difference lists (Hughes, 1984).

```
type 'a diff =
  'a list -> 'a list

let singleton (x : 'a) : 'a diff =
  fun xs -> x :: xs
let concat (xs : 'a diff) (ys : 'a diff) : 'a diff =
  fun zs -> xs (ys zs)
```

The idea is to represent a list xs as a function that maps ys to xs @ ys.

singleton is "cons", and concat is function composition!

They both have time complexity $O(1)$.

Conclusion

A type of all closures

A type of closures can be defined in OCaml as follows:

```ocaml
type ('a, 'b) closure =
  | Clo:
              ?          (* A (closed) function...       *)
         * ?             (* ...and its environment...    *)
    -> ('a, 'b) closure  (* ...together form a closure. *)
```

Here, the closure and its environment are distinct memory blocks;
this is slightly different from what was shown earlier today.

To read more about type-preserving closure conversion,
see Minamide *et al.* (1996) and my ancient slides (2009).

Defun°

Digression
Objects
λ-lifting
SKI

Conclusion

Difference lists, closure-converted

Let us manually apply closure conversion to difference lists.

A difference list is a closure:

```
type 'a diff =
  ('a list, 'a list) closure
```

singleton and concat allocate and return a closure:

```
let singleton_code =
  fun (xs, x) -> x :: xs
let singleton (x : 'a) : 'a diff =
  Clo (singleton_code, x)

let concat_code =
  fun (zs, (xs, ys)) -> apply xs (apply ys zs)
let concat (xs : 'a diff) (ys : 'a diff) : 'a diff =
  Clo (concat_code, (xs, ys))
```

The closed functions singleton_code and concat_code are hoisted out.

Conclusion

Difference lists, closure-converted

The difference-list-based fringe computation, closure-converted:

```
let rec fringe_ (t : tree) : int diff =
  match t with
  | Leaf i        -> singleton i
  | Node (t1, t2) -> concat (fringe_ t1) (fringe_ t2)

let fringe t =
  apply (fringe_ t) []
```

It should be clear that `fringe_ t` builds a tree of closures, whose shape is identical to the shape of the tree `t`.

Then, the call `apply _ []` interprets this tree of closures.

Is this efficient?

Conclusion

Difference lists, closure-converted

The difference-list-based fringe computation, closure-converted:

```
let rec fringe_ (t : tree) : int diff =
  match t with
  | Leaf i        -> singleton i
  | Node (t1, t2) -> concat (fringe_ t1) (fringe_ t2)

let fringe t =
  apply (fringe_ t) []
```

It should be clear that `fringe_ t` builds a tree of closures,
whose shape is identical to the shape of the tree `t`.

Then, the call `apply _ []` interprets this tree of closures.

Is this efficient?

Each of the two phases costs $O(n)$. Asymptotic complexity is good.

Yet, phase 1, a tree copy, is useless. The constant factor is not great.

Exercise: write `fringe` so that cost is $O(n)$ and no tree copy takes place.

Conclusion

Minimal environments

My pencil-and-paper definition of closure conversion allocates closures
with minimal environments, where the closure stores just what it needs:

$$[\![\lambda x.t]\!] = \textit{let code} = \qquad\qquad \text{where } \{x_1, \ldots, x_n\} = fv(\lambda x.t)$$
$$\lambda(clo, x).$$
$$\textit{let } x_i = \pi_i \; clo \; \textit{in} \quad \text{for each } i \in \{1, \ldots, n\}$$
$$[\![t]\!]$$
$$\textit{in}$$
$$(code, x_1, \ldots, x_n)$$

In contrast, for greater simplicity, my Rocq definition in `ClosureConversion`
allocates closures with full environments.

Full environments lead to larger closures and space leaks,
so they are not viable in practice.

Conclusion

Recursive functions

How should recursive function definitions be transformed?

$$\llbracket \lambda x.t \rrbracket = let\ code = \qquad\qquad\qquad where\ \{x_1, \ldots, x_n\} = fv(\lambda x.t)$$
$$\qquad\qquad \lambda(clo, x).$$
$$\qquad\qquad\qquad let\ x_i = \pi_i\ clo\ in \qquad for\ each\ i \in \{1, \ldots, n\}$$
$$\qquad\qquad\qquad \llbracket t \rrbracket$$
$$\qquad\qquad in$$
$$\qquad\qquad (code, x_1, \ldots, x_n)$$

$$\llbracket \mu f.\lambda x.t \rrbracket = ?$$

$$\llbracket t_1\ t_2 \rrbracket = let\ clo = \llbracket t_1 \rrbracket\ in$$
$$\qquad\qquad let\ (code, \ldots) = clo\ in$$
$$\qquad\qquad code\ (clo, \llbracket t_2 \rrbracket)$$

The transformation of function calls cannot be modified: the caller does not (want to) know whether the callee is a recursive function.

In other words, we must maintain a uniform calling convention.

Digression
Objects
λ-lifting
SKI

Conclusion

Recursive functions

We must arrange for the variable *f* to be bound to an appropriate value:

$$\llbracket \mu f.\lambda x.t \rrbracket = let\ code = \qquad\qquad\qquad where\ \{x_1,\dots,x_n\} = fv(\mu f.\lambda x.t)$$
$$\lambda(clo, x).$$
$$let\ f = clo\ in$$
$$let\ x_i = \pi_i\ clo\ in \quad for\ each\ i \in \{1,\dots,n\}$$
$$\llbracket t \rrbracket$$
$$in$$
$$(code, x_1,\dots,x_n)$$

The closure *clo* happens to be such a value.

Exercise: extend the Rocq formalisation with recursive functions.

Conclusion

Mutually recursive functions

What about mutually recursive function definitions?

Suppose the source calculus has mutually recursive function definitions:

$$t ::= \ldots \mid \text{let rec } f_1 = \lambda x_1.t_1 \text{ and } f_2 = \lambda x_2.t_2 \text{ in } t$$

Suppose the target calculus has mutually recursive value definitions:

$$t ::= \ldots \mid \text{let rec } f_1 = v_1 \text{ and } f_2 = v_2 \text{ in } t$$

Exercise: propose a (deterministic, call-by-value) operational semantics with support for these constructs. Impose a syntactic contractiveness condition to rule out nonsensical definitions such as **let rec** x = x.

Answer: Nordlander, Carlsson and Gill (2008) propose an operational semantics. Reynaud, Scherer and Yallop (2019) propose a type system that rules out nonsensical definitions.

Definition
Soundness
Type preservat°
Digression

Defun°

Digression
Objects
λ-lifting
SKI

Conclusion

Mutually recursive functions

It is then easy to define a transformation of recursive functions:

$$
\begin{aligned}
\llbracket \textit{let rec } f_1 &= \lambda x_1.t_1 \\
\textit{and } f_2 &= \lambda x_2.t_2 \\
&\textit{in } u \rrbracket = \textit{let rec } f_1 = \llbracket \lambda x_1.t_1 \rrbracket \\
&\qquad\qquad\quad \textit{and } f_2 = \llbracket \lambda x_2.t_2 \rrbracket \\
&\qquad\qquad\quad \textit{in } \llbracket u \rrbracket
\end{aligned}
$$

This transformation is correct, albeit slightly inefficient.

We get two closures, each of which contains
a pointer to itself and
a pointer to the other closure.

Indeed, f_1 and f_2 can be free in $\lambda x_1.t_1$ and $\lambda x_2.t_2$.
If so, the tuples $\llbracket \lambda x_1.t_1 \rrbracket$ and $\llbracket \lambda x_2.t_2 \rrbracket$ have slots for f_1 and f_2.

Conclusion

Mutually recursive functions

A slightly more efficient transformation is as follows:

$$\llbracket \textit{let rec } f_1 = \lambda x_1.t_1 \\ \textit{and } f_2 = \lambda x_2.t_2 \\ \textit{in } u \rrbracket = \textit{let rec } f_1 = \llbracket \mu f_1.\lambda x_1.t_1 \rrbracket \\ \textit{and } f_2 = \llbracket \mu f_2.\lambda x_2.t_2 \rrbracket \\ \textit{in } \llbracket u \rrbracket$$

We get two closures, each of which points to the other.

The redundant pointer from each closure to itself has been removed.

SKI

Conclusion

Further improvements

Naïve closure conversion can produce inefficient code.

Selective closure conversion applies when the environment would have zero slots, and avoids building a closure in that case.

Lightweight closure conversion applies when a value that should be stored in the environment happens to be available at every call site. Then, instead of being stored, this value becomes an extra argument.

Both ideas involve a modified closure invocation protocol, therefore require an agreement between callers and callees, therefore require a control flow analysis: one must know which closures may be invoked where.

Steckler and Wand, Selective and lightweight closure conversion, 1994.

Conclusion

Further improvements

Applications of (curried) multi-parameter functions
to multiple actual arguments should be identified and optimized.

- e.g., map f xs should not be compiled as (map f) xs,
  where (map f) allocates and returns a closure!

This is done in OCaml and in CakeML,
where this transformation is verified.

Owens *et al.*, Verifying Efficient Function Calls in CakeML, 2017.

Conclusion

Trivia: closures and mutable variables

In ML, F#, Java, ..., closures capture immutable variables only.

In certain "interesting" programming languages, closures can refer to mutable variables, too. E.g., in JavaScript:

```
var messages = ["Wow!", "Hi!", "Closures are fun!"];
for (var i = 0; i < messages.length; i++) {
  setTimeout(function () {
    say(messages[i]);
  }, i * 1500);
}
```

This program, of course, ...

Conclusion

Activation of TRPV1 by capsaicin
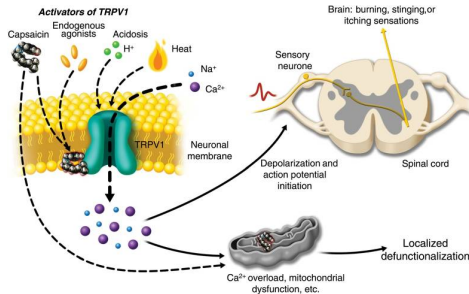

Activation of TRPV1 by capsaicin results in sensory neuronal depolarization, and can induce local sensitization to activation by heat, acidosis, and endogenous agonists. Topical exposure to capsaicin leads to the sensations of heat, burning, stinging, or itching. High concentrations of capsaicin or repeated applications can produce a persistent local effect on cutaneous nociceptors, which is best described as **defunctionalization** and constituted by reduced spontaneous activity and a loss of responsiveness to a wide range of sensory stimuli.

Conclusion

Defunctionalization

Defun°, like closure conversion, aims to eliminate first-class functions.

Defun° differs in the representation of closures:

- instead of a code pointer and an environment,
- use a tag and an environment.

Thus, instead of (closed) first-class functions,
the target language must have algebraic data types.

Functions become data!

Pottier

Closure
conversion
Motivation
Definition
Soundness
Type preservat°
Digression

Defun°

Digression
Objects
λ-lifting
SKI

Conclusion

Definition of defunctionalization

The toplevel function *apply* interprets a closure as a function.

The whole transformed program is placed in the scope of this definition:

> *let rec apply* (*this*, *that*) =
>   *match this with*
>   · · ·
> | $C(x_1, \ldots, x_n) \rightarrow$ for each function $\lambda^C x.t$ in the source
>   *let x = that in*
> $[\![t]\!]$
>   · · ·

apply must be recursively defined, as $[\![t]\!]$ can refer to *apply*.

Difference lists

Recall difference lists:

```
type 'a diff =
  'a list -> 'a list

let singleton (x : 'a) : 'a diff =
  fun xs -> x :: xs
let concat (xs : 'a diff) (ys : 'a diff) : 'a diff =
  fun zs -> xs (ys zs)
```

As an illustration, let us manually defunctionalize this code.

There are two first-class functions of interest in this code.

MPRI FUN
Compiling
functions
away

François
Pottier

Difference lists, defunctionalized

Thus, we introduce an algebraic data type with two data constructors:

```
type 'a diff =
  | Singleton of 'a
  | Concat of 'a diff * 'a diff
let singleton (x : 'a) : 'a diff =
  Singleton x
let concat (xs : 'a diff) (ys : 'a diff) : 'a diff =
  Concat (xs, ys)
```

The functions `singleton` and `concat` just build a closure.

There remains to define `apply`.

Conclusion

Difference lists, defunctionalized

The fringe computation is the same as in the closure-converted version:

```
let rec fringe_ (t : tree) : int diff =
  match t with
  | Leaf i        -> singleton i
  | Node (t1, t2) -> concat (fringe_ t1) (fringe_ t2)

let fringe t =
  apply (fringe_ t) []
```

The types tree and **int** diff are isomorphic!

It is clear (again) that fringe_ is just a tree copy.

Conclusion

Sets as characteristic functions

There are three places where a closure of type `set` is built:

```
let empty : set =
  fun y -> false
let singleton (x : int) : set =
  fun y -> y = x
let union (s1 : set) (s2 : set) : set =
  fun y -> s1 y || s2 y
```

What fields do these closures carry?

- in `empty`, no fields;
- in `singleton`, one field of type `int` corresponding to `x`;
- in `union`, two fields of type `set` corresponding to `s1` and `s2`.

Let us give these three kinds of closures three distinct labels, say **E**, **S**, **U**.

Conclusion

Sets as characteristic functions, defunctionalized

A "set" is really a closure of one of these three kinds.

Through defunctionalization, `set` becomes an algebraic data type:

```
type set =
  | E
  | S of int
  | U of set * set
```

The three constructor functions become:

```
let empty : set =                        E
let singleton (x : int) : set =          S (x)
let union (s1 : set) (s2 : set) : set = U (s1, s2)
```

What is this data type?

Conclusion

Sets as characteristic functions, defunctionalized

A "set" is really a closure of one of these three kinds.

Through defunctionalization, `set` becomes an algebraic data type:

```
type set =
  | E
  | S of int
  | U of set * set
```

The three constructor functions become:

```
let empty : set =                         E
let singleton (x : int) : set =           S (x)
let union (s1 : set) (s2 : set) : set = U (s1, s2)
```

What is this data type?

A data type of trees with leaves **E** and **S** and binary nodes **U**.

MPRI FUN
Compiling
functions
away

François
Pottier

Sets as characteristic functions, defunctionalized

apply interprets a `set` as a characteristic function of type `int` -> `bool`.

```
let rec apply (s : set) (y : int) : bool =
  match s with
  | E          -> false
  | S (x)      -> y = x
  | U (s1, s2) -> apply s1 y || apply s2 y
```

The membership test becomes:

```
let mem (x : int) (s : set) : bool =
  apply s x
```

Conclusion

Type-preserving defunctionalization

We have seen earlier that closure conversion can be type-preserving.
This requires existential types in the target calculus.

Can defunctionalization be made type-preserving?

Yes, it can. This requires generalized algebraic data types (GADTs) in the target calculus.

Pottier and Gauthier,
Polymorphic typed defunctionalization and concretization, 2006.

Conclusion

Type-preserving defunctionalization

Why are GADTs needed? Well, try defunctionalizing this OCaml code:

```
let foo (xs : int list) : int list =
  filter (fun x -> x <> 0) (map (fun x -> x + 1) xs)
```

The solution appears on the following slides.

λ-lifting
SKI

Conclusion

Type-preserving defunctionalization

```
let foo (xs : int list) : int list =
  filter (fun x -> x <> 0) (map (fun x -> x + 1) xs)
```

A GADT is needed to describe the two kinds of closures that appear:

```
type (_, _) closure =
  | NEqZero   : (int, bool) closure
  | Increment : (int,  int) closure
```

These closures are trivial: there is just a tag, no fields.

Conclusion

Type-preserving defunctionalization

```
let foo (xs : int list) : int list =
  filter (fun x -> x <> 0) (map (fun x -> x + 1) xs)
```

These closures are interpreted by the function apply:

```
let rec apply =
  fun (type a b) (this : (a, b) closure) (that : a) : b ->
    match this with
    | NEqZero ->
        let x = that in
        x <> 0
    | Increment ->
        let x = that in
        x + 1
```

Conclusion

Type-preserving defunctionalization

```
let foo (xs : int list) : int list =
  filter (fun x -> x <> 0) (map (fun x -> x + 1) xs)
```

The functions `filter` and `map` use `apply`:

```
let rec filter p xs =
  match xs with
  | []      -> []
  | x :: xs -> if apply p x then x :: filter p xs
               else filter p xs

let rec map f xs =
  match xs with
  | []      -> []
  | x :: xs -> apply f x :: map f xs
```

Conclusion

Compiling functions as objects

On the surface, Scala has functions and objects, but functions are sugar.

The function type `T => R` is sugar for `Function1[T, R]`.

```scala
trait Function1[-T, +R] { // Defined in the base library.
  def apply(v: T): R      // Any object with an apply method
}                         // is a "function"!
```

An anonymous function:

```scala
(x: Int) => x + y
```

is sugar for an object creation expression:

```scala
new Function1[Int, Int] {
  def apply(x: Int): Int = x + y
}
```

Functions (w/ free variables) are translated to objects (w/ free variables).

λ-lifting
SKI

Conclusion

Compiling objects with free variables

This object creation expression has a free variable y:

```scala
new Function1[Int, Int] {
  def apply(x: Int): Int = x + y
}
```

It can be viewed as sugar for

```scala
new C (y)
```

where `C` is a unique name. The class `C` is defined at the top level:

```scala
class C (y: Int) {
  def apply(x: Int): Int = x + y
}
```

Objects (w/ free variables) are translated to parameterized classes.

This is a modular form of defunctionalization.

Conclusion

Compiling parameterized classes

A parameterized class:

```
class C (y: Int) {
  def apply(x: Int): Int = x + y
}
```

is sugar for a class with an explicit field and a constructor:

```
class C {
  var y: Int = _
  def this (y: Int) = {
    this()
    this.y = y
  }
  def apply(x: Int): Int = x + y
}
```

Parameterized classes are translated down to ordinary classes.

Conclusion

Functions in Scala

Thus, functions in Scala are represented by heap-allocated closures, with one field per free variable, just as in OCaml.

Conclusion

λ-lifting

First-class functions (with free variables) can also be be compiled down to a combination of closed (toplevel) functions and partial applications.

This is known as λ-lifting.

Johnsson, Lambda lifting:
transforming programs to recursive equations, 1985.

λ-lifting

eval evaluates a polynomial `cs` at a point `x`.

```
let eval (cs : int list) (x : int) : int =
  let cons (c : int) (a : int -> int) =
    let aux x_n = c * x_n + a (x * x_n) in
    aux
  and null x_n =
    0
  in foldr cons null cs 1
```

`aux` has three free variables `c`, `a`, `x`, while `cons` has one free variable `x`.

Step 1: make them parameters.

SKI

Conclusion

λ-lifting

Every function in the resulting code is closed.

```
let eval cs x =
  let cons x c a =
    let aux c a x x_n = c * x_n + a (x * x_n) in
    aux c a x
  and null x_n =
    0
  in foldr (cons x) null cs 1
```

Step 2: hoist every function to the top level.

SKI

Conclusion

λ-lifting

We get a group of toplevel functions, also known as supercombinators:

```
let aux c a x x_n =
  c * x_n + a (x * x_n)
let cons x c a =
  aux c a x
let null x_n =
  0
let eval cs x =
  foldr (cons x) null cs 1
```

This code contains partial applications, though. (Find them!)

Conclusion

λ-lifting

λ-lifting was popular in the 1980s because people were interested in abstract machines or "graph reduction" systems that dealt with partial applications directly.

> Peyton Jones, The implementation
> of functional programming languages, 1987.

> Bird, A formal development
> of an efficient supercombinator compiler, 1987.

Today, these ideas are largely obsolete.

Conclusion

Compiling to SKI combinators

An idea from the 1950s (Curry and Feys, 1958).

The combinators S, K, I are defined as follows:

$$
\begin{array}{rcl}
S \ f \ g \ x & = & f \ x \ (g \ x) \\
K \ x \ y & = & x \\
I \ x & = & x
\end{array}
$$

What is special about them?

Conclusion

Compiling to SKI combinators

An idea from the 1950s (Curry and Feys, 1958).

The combinators S, K, I are defined as follows:

$$
\begin{array}{rcl}
S\,f\,g\,x & = & f\,x\,(g\,x) \\
K\,x\,y & = & x \\
I\,x & = & x
\end{array}
$$

What is special about them?

Every λ-term can be compiled to code
that involves just S, K, I and applications.

No λ-abstractions, no variables!

Conclusion

Compiling to SKI combinators

Apply the following rules, beginning with innermost λ-abstractions:

replace	$\lambda x.x$	with	I	
replace	$\lambda x.t$	with	$K\ t$	if $x \notin fv(t)$
replace	$\lambda x.(t_1\ t_2)$	with	$S\ (\lambda x.t_1)\ (\lambda x.t_2)$	

Thus, λ's are pushed towards the leaves, where they vanish.

For instance,

$$
\begin{aligned}
& (\lambda x.+\ x\ x)\ 5 \\
\rightarrow\quad & S\ (\lambda x.+\ x)\ (\lambda x.x)\ 5 \\
\rightarrow\quad & S\ (S\ (\lambda x.+)\ (\lambda x.x))\ (\lambda x.x)\ 5 \\
\rightarrow\quad & S\ (S\ (K\ +)\ (\lambda x.x))\ (\lambda x.x)\ 5 \\
\rightarrow\quad & S\ (S\ (K\ +)\ I)\ (\lambda x.x)\ 5 \\
\rightarrow\quad & S\ (S\ (K\ +)\ I)\ I\ 5
\end{aligned}
$$

Recursion can be dealt with by adding the combinator Y.

This naïve approach can cause a quadratic blowup, though.

Kiselyov, λ to SKI, Semantically, 2018.

Conclusion

Compiling to SKI combinators

S, *K*, *I* can be viewed as the instruction set of an abstract machine.

This idea was used to compile SASL and Miranda (Turner, 1976–79).

There were plans in the 1980s to do this in hardware!

Peyton Jones, The implementation
of functional programming languages, 1987.

Of course, it is much more efficient to compile down to machine code for
a standard (von Neumann) processor, which is highly optimized.

A few things to remember

- First-class functions are a key feature of modern prog. languages.
- Closure conversion and defunctionalization help understand them.
- Like objects, closures bundle code and data
  — "behavior" and "state", in object-oriented speak.
- We have encountered a semantic preservation statement and discussed its exact meaning. Always question what you have proved!
